

Processor Architecture

Victor Eijkhout

Fall 2023

The performance of a parallel code has as one component the behaviour of the single processor or single-threaded code. In this section we discuss the basics of how a processor executes instructions, and how it handles the data these instructions operate on.

Structure of a modern processor

The ideal processor:

- (Stored program)
- An instruction contains the operation and two operand locations
- Processor decodes instruction, gets operands, computes and writes back the result
- Repeat

- Single instruction stream versus multiple cores / floating point units
- Single instruction stream versus Instruction Level Parallelism
- Unit-time-addressable memory versus large latencies

Modern processors contain lots of magic to make them seem like Von Neumann machines.

Traditional: processor speed was paramount. Operation counting.

Nowadays: memory is slower than processors

This course

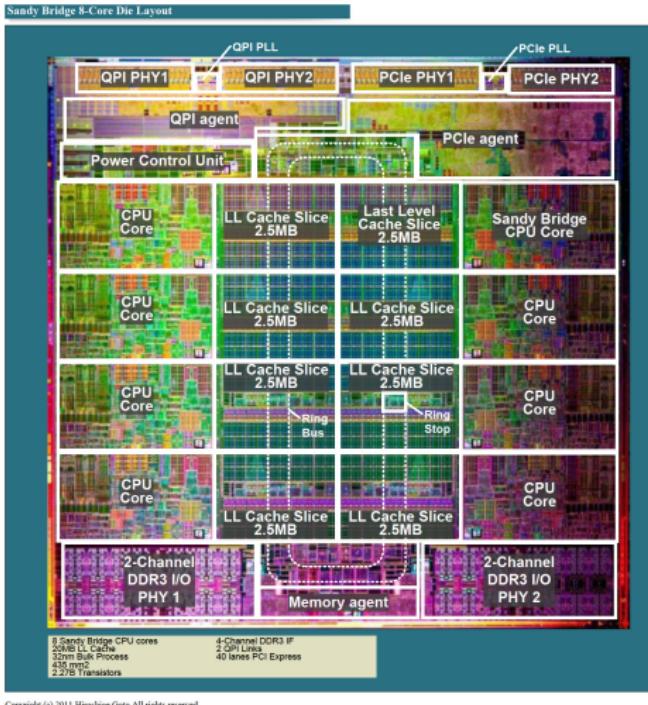

Study data movement aspects

Algorithm design for processor reality

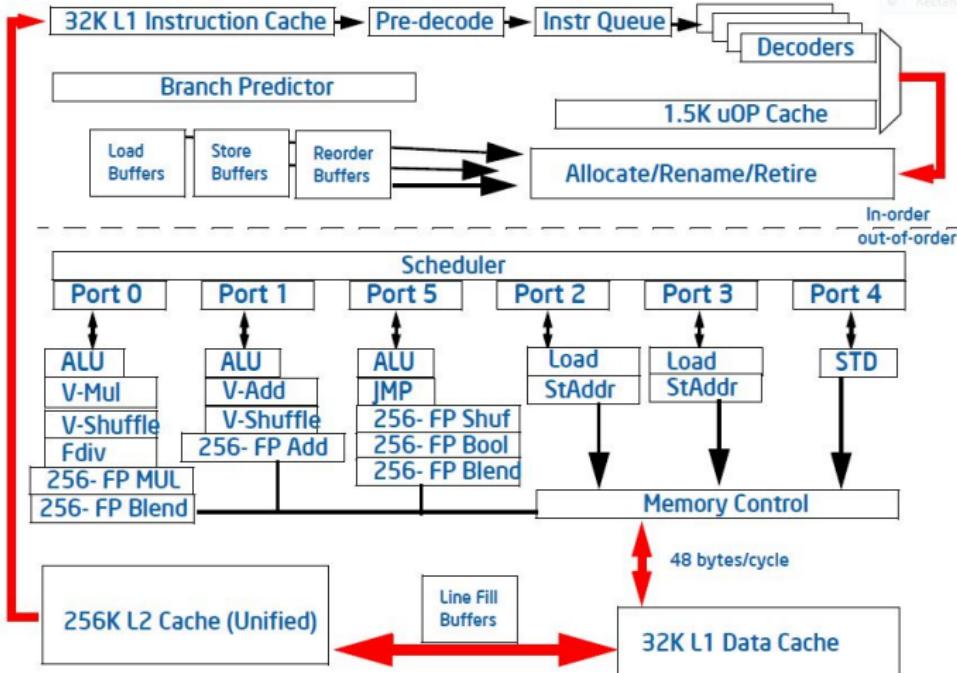

A first look at a processor

TACC

Structure of a core

TACC

An operation consists of several stages.

Addition:

- Decoding the instruction operands.
- Data fetch into register
- Aligning the exponents:

$$\begin{array}{l} .35 \times 10^{-1} + .6 \times 10^{-2} \\ .35 \times 10^{-1} + .06 \times 10^{-1}. \end{array} \quad \text{becomes}$$

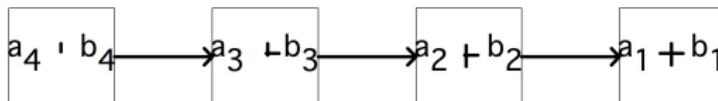

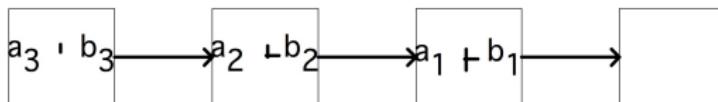

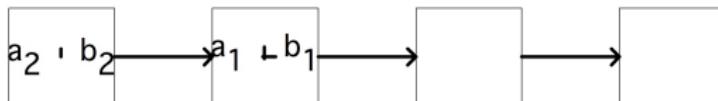

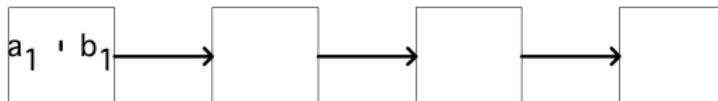

- Adding mantissas, giving .41.
- Normalizing the result, giving $.41 \times 10^{-1}$.
- Storing the result.

pipeline stages

Discrete hardware for each stage:

$$c_i \leftarrow a_i + b_i$$

Operation timing:

$$\begin{cases} n & \text{operations} \\ \ell & \text{number of stages} \Rightarrow t(n) = n\ell\tau \\ \tau & \text{clock cycle} \end{cases}$$

With pipelining:

$$t(n) = [s + \ell + n - 1]\tau$$

where s is a setup cost

\Rightarrow Asymptotic speedup is ℓ

$n_{1/2}$: value for which speedup is $\ell/2$

Pipelining works for:
vector addition/multiplication
Division/square root maybe pipelined, but much slower

Pipelining does not immediately work:

```
for (i) {  
    x[i+1] = a[i]*x[i] + b[i];  
}
```

Transform:

$$\begin{aligned}x_{n+2} &= a_{n+1}x_{n+1} + b_{n+1} \\&= a_{n+1}(a_nx_n + b_n) + b_{n+1} \\&= a_{n+1}a_nx_n + a_{n+1}b_n + b_{n+1}\end{aligned}$$

- Instruction-Level Parallelism: more general notion of independent instructions
- Requires independent instructions
- As frequency goes up, pipeline gets longer: more demands on compiler

- multiple-issue of independent instructions
- branch prediction and speculative execution
- out-of-order execution
- prefetching

Problems: complicated circuitry, hard to maintain performance

- Long pipeline needs many independent instructions:
demands on compiler
- Conditionals break the stream of independent instructions
 - Processor tries to predict branches
 - branch misprediction penalty:
pipeline needs to be flushed and refilled
 - avoid conditionals in inner loops!

- Addition/multiplication: pipelined
- Division (and square root): much slower

```
for ( i )
    a[i] = b[i] / c
```

Can you improve on this?

- Fused Multiply-Add (FMA) $s += a * b$
where can you use this?

Performance is a function of

- Clock frequency,
- SIMD width
- Load/store unit behavior

Floating point capabilities of several processor architectures

DAXPY cycle number for 8 operands

Processor	year	add/mult/fma units (count \times width)	daxpy cycles (arith vs load/store)
MIPS R10000	1996	$1 \times 1 + 1 \times 1 + 0$	8/24
Alpha EV5	1996	$1 \times 1 + 1 \times 1 + 0$	8/12
IBM Power5	2004	$0 + 0 + 2 \times 1$	4/12
AMD Bulldozer	2011	$2 \times 2 + 2 \times 2 + 0$	2/4
Intel Sandy Bridge	2012	$1 \times 4 + 1 \times 4 + 0$	2/4
Intel Haswell	2014	$0 + 0 + 2 \times 4$	1/2

Memory hierarchy: caches, register, TLB.

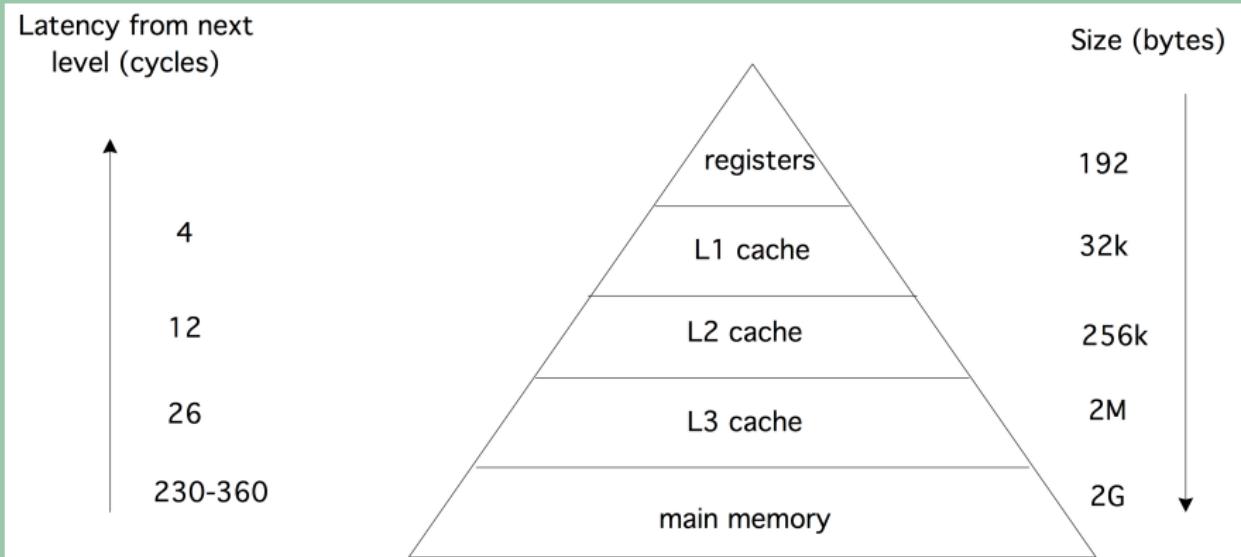

- DRAM memory is slow, so let's put small SRAM close to the processor
- This helps if data is reused
- Does the algorithm have reuse?
- Does the implementation reuse data?

Important theoretical concept:

- latency is delay between request for data and availability
- bandwidth is rate at which data arrives thereafter

Registers

a := b + c

- load the value of b from memory into a register,
- load the value of c from memory into another register,
- compute the sum and write that into yet another register, and
- write the sum value back to the memory location of a.

Assembly code
(note: Intel two-operand syntax)

```
addl %eax, %edx
```

- Registers are named
- Can be explicitly addressed by the programmer
- ... as opposed to caches.
- Assembly coding or inline assembly (compiler dependent)
- ... but typically generated by compiler

1. Resident in register

```
a := b + c
```

```
d := a + e
```

a stays resident in register, avoid store and load

2. subexpression elimination:

```
t1 = sin(alpha) * x + cos(alpha) * y;
```

```
t2 = -cos(alpha) * x + sin(alpha) * y;
```

becomes:

```
s = sin(alpha); c = cos(alpha);
```

```
t1 = s * x + c * y;
```

```
t2 = -c * x + s * y
```

often done by compiler

Caches

Fast SRAM in between memory and registers: mostly serves data reuse

```
... = ... x ..... // instruction using x  
.....           // several instructions not involving x  
... = ... x ..... // instruction using x
```

- load x from memory into cache, and from cache into register; operate on it;
- do the intervening instructions;
- request x from memory, but since it is still in the cache, load it from the cache into register; operate on it.
- essential concept: data reuse

- Levels 1,2,3(,4): L1, L2, etc.
- Increasing size, increasing latency, decreasing bandwidth
- (Note: L3/L4 can be fairly big; beware benchmarking)
- Cache hit / cache miss: one level is consulted, then the next
- L1 has separate data / instruction cache, other levels mixed
- Caches do not have enough bandwidth to serve the processor:
coding for reuse on all levels.

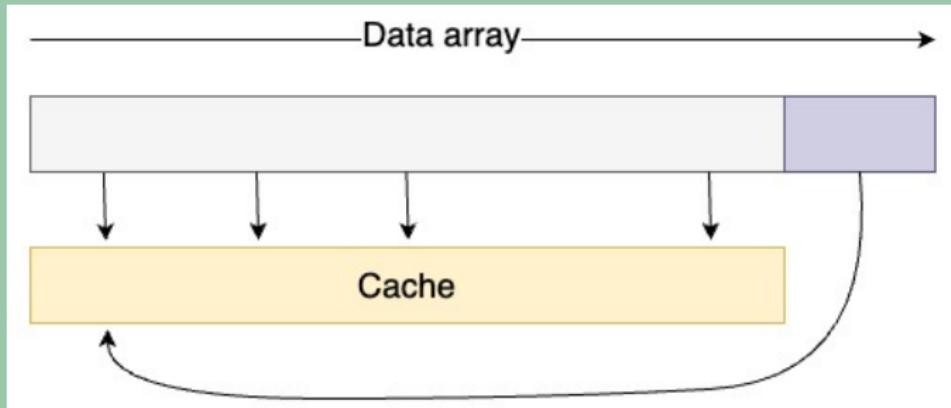

- Compulsory miss: first time data is referenced
- Capacity miss: data was in cache, but has been flushed (overwritten) by LRU policy
- Conflict miss: two items get mapped to the same cache location, even if there are no capacity problems
- Invalidation miss: data becomes invalid because of activity of another core

- Data has been requested, used a second time: temporal locality
- ⇒ Can't wait too long between uses
- (Data can be loaded because it's close to data requested: spatial locality. Later.)

(Why is that last block going where it is going?)

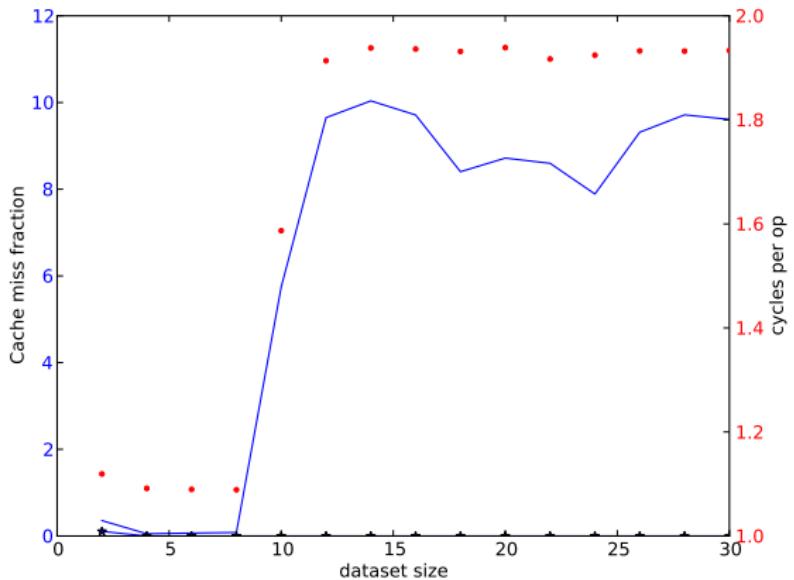

- Loading data multiple times
- LRU: oldest item evicted if needed
- Reuse if not too much data

```
for ( lots of times ) // sequential loop  
    load and process data // probably parallel loop
```

Illustration of capacity

TACC

What determines where new data goes /
what old data is overwritten?

- Least Recently Used (LRU): most common
- First-In / First-Out (FIFO): IBM Power4. Not a good idea.
- Random Replacement. Sometimes used.

It's actually more subtle than pure LRU ...

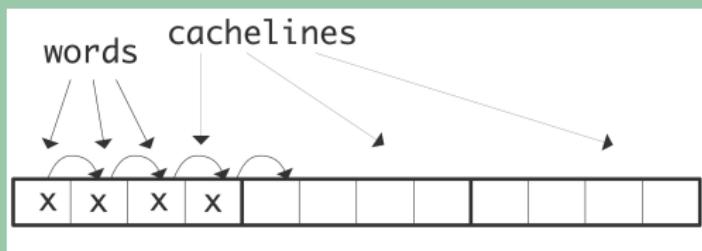

- Memory requests go by byte or word
- Memory transfers go by cache line:
typically 64 bytes / 8 double precision numbers
- Cache line transfer costs bandwidth
- ⇒ important to use all elements

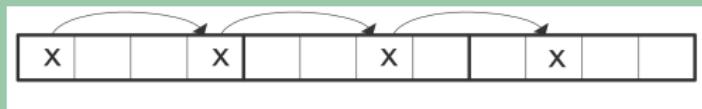

- Always 8 numbers transferred
- With stride $s > 1$: $8/s$ elements used
- Loss of efficiency if bandwidth-limited

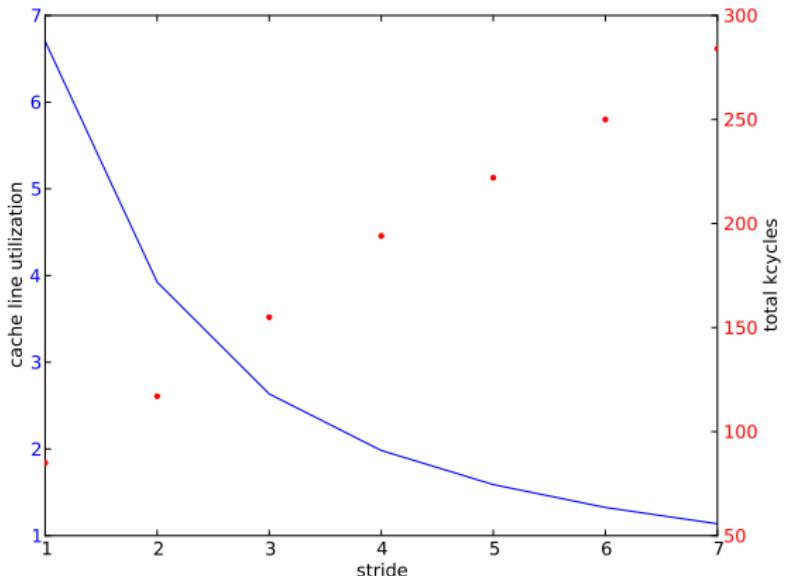

```
for (i=0; i<N; i++)  
    ... = ... x[i] ...
```

```
for (i=0; i<N; i+=stride)  
    ... = ... x[i] ...
```

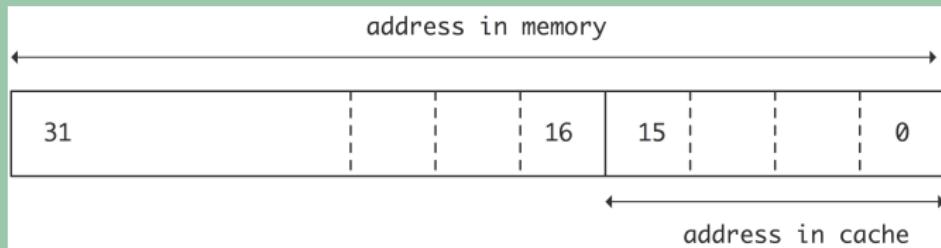

```
for (i=0,n=0; i<L1WORDS; i++,n+=stride)
    array[n] = 2.3*array[n]+1.2;
```

Cache is smaller than memory, so we need a mapping scheme
memory address \mapsto cache address

- Ideal: any address can go anywhere; LRU policy for replacement
- pro: optimal; con: slow, expensive to manufacture
- Simple: direct mapping by truncating addresses
- pro: fast and cheap; con: I'll show you in a minute
- Practical: limited associativity
'enough but not too much'

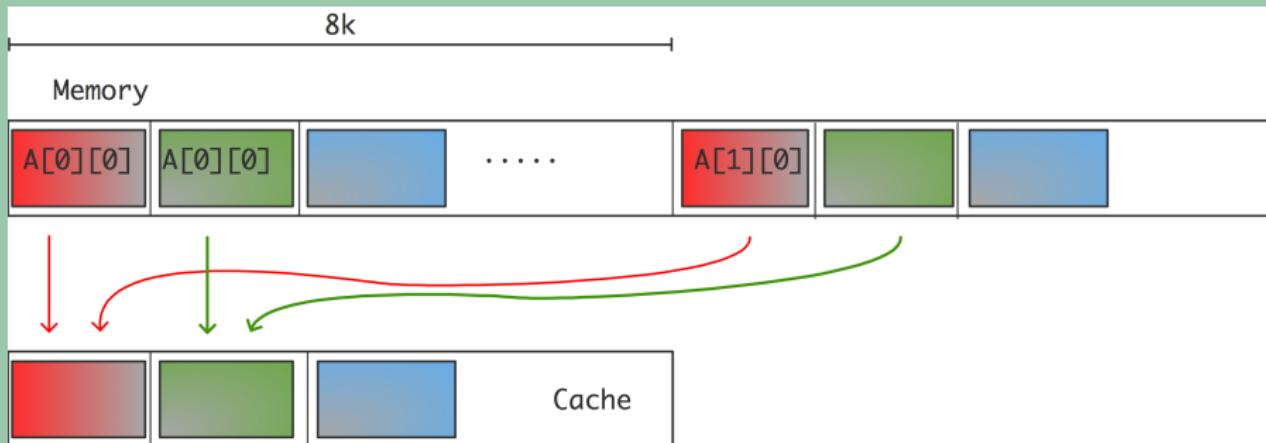

Direct mapping of 32-bit addresses into a 64K cache

- Use last number of bits to find cache address
- If you traverse an array, a contiguous chunk will be mapped to cache without conflict.
- If (memory) addresses are cache size apart, they get mapped to the same cache location

Mapping conflicts in a direct-mapped cache.

```
real*8 A(8192,3);
do i=1,512
    a(i,3) = ( a(i,1)+a(i,2) )/2
end do
```

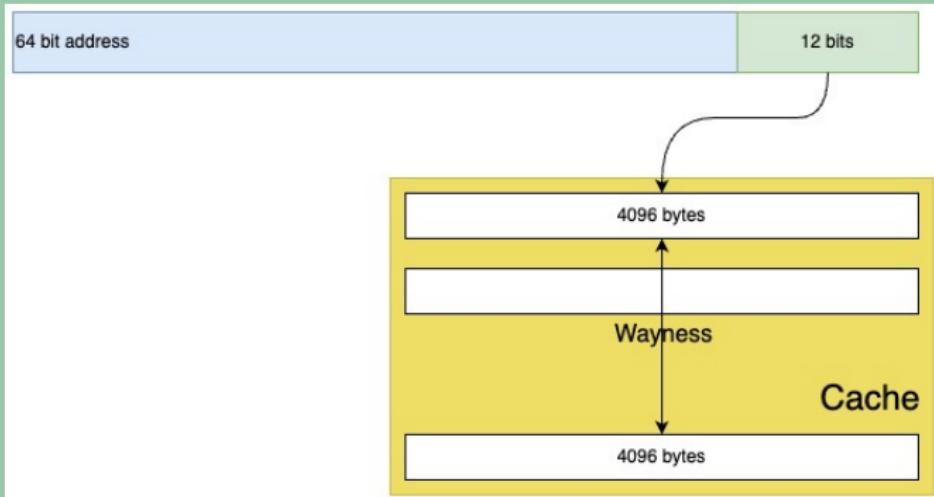

In each iteration 3 elements map to the same cache location:
constant overwriting ('eviction', cache thrasing):
low performance

- Allow each memory address to go to multiple (but not all) cache addresses; typically 2,4,8
- Prevents problems with multiple arrays
- Reasonable fast
- Often lower associativity for L1 than L2, L3

Associativity	L1	L2
Intel (Woodcrest)	8	8
AMD (Bulldozer)	2	8

Associative cache structure

Illustration of associativity

	{0, 12, 24, ... }				{0, 12, 24, ... }	{4, 16, 28, ... }
	{1, 13, 25, ... }				{8, 20, 32, ... }	
	{2, 14, 26, ... }				{1, 13, 25, ... }	{5, 17, 29, ... }
	{3, 15, 27, ... }				{9, 21, 33, ... }	
	{4, 16, 28, ... }				{2, 14, 26, ... }	{6, 18, 30, ... }
	{5, 17, 29, ... }				{10, 22, 34, ... }	
	{6, 18, 30, ... }				{3, 15, 27, ... }	{7, 19, 31, ... }
	{7, 19, 31, ... }				{11, 23, 35, ... }	
	{8, 20, 32, ... }					
	{9, 21, 33, ... }					
	{10, 22, 34, ... }					
	{11, 23, 35, ... }					

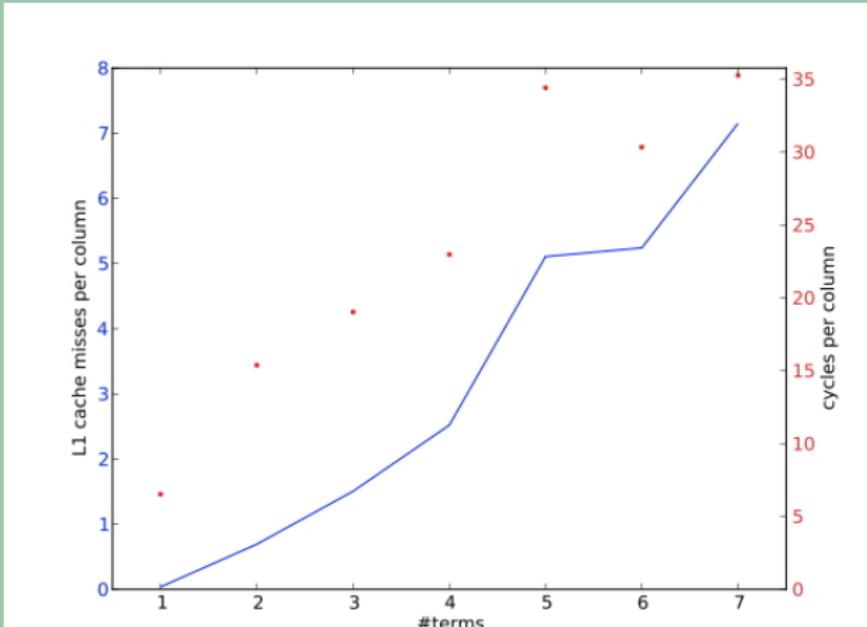

Two caches of 12 elements: direct mapped (left) and 3-way associative (right)

Direct map: 0–12 is conflict

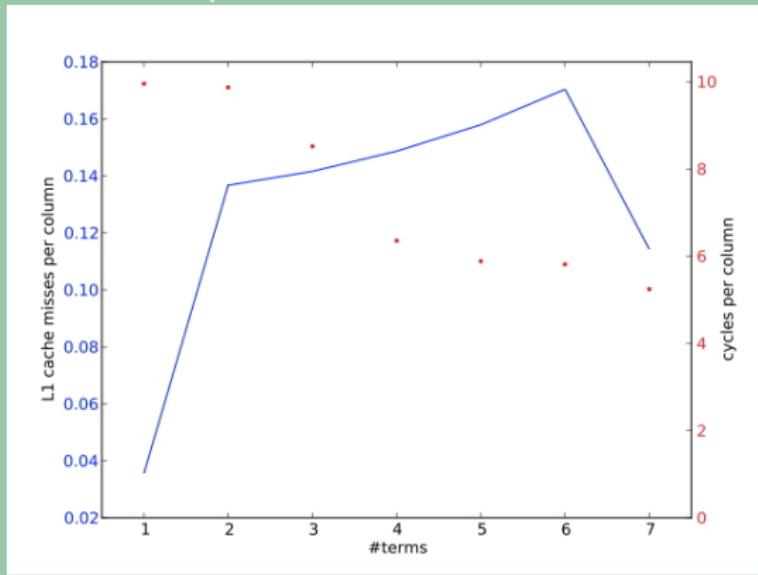

Associative: no conflict

$$\forall_j: y_j = y_j + \sum_{i=1}^m x_{i,j}$$

Do not user powers of 2.

The number of L1 cache misses and the number of cycles for each j column accumulation, vector length $4096 + 8$

Write a small cache simulator in your favorite language. Assume a k -way associative cache of 32 entries and an architecture with 16 bit addresses.

- Compare sequential performance to single-threaded OMP
- For some problem sizes observe a difference in performance
- Use Intel option `-qopt-report=3` and inspect the report.
- Compare different compilers: Intel 19 behaves differently from 24!
Also gcc13.

```
for ( int iloop=0; iloop<nloops; ++iloop ) {
    for ( int i=0; i<vectorsize; ++i ) {
        outvec[i] += invec[i]*loopcoeff[iloop];
    }
}
```

Analyze and report

More memory system topics

Simple model for sending n words:

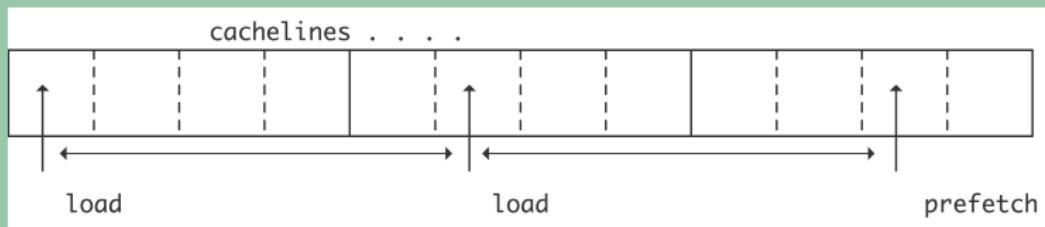

$$t = \alpha + \beta n$$

Quoted bandwidth figures are always optimistic:

- bandwidth shared between cores
 - not enough bandwidth for all cores:
⇒ speedup less than linear
- bandwidth wasted on coherence
- NUMA: pulling data from other socket
- assumes optimal scheduling of DRAM banks

- Do you have to wait for every item from memory?
- Memory controller can infer streams: prefetch
- Sometimes controllable through assembly, directives, libraries (AltiVec)
- One form of latency hiding

Memory is organized in pages:

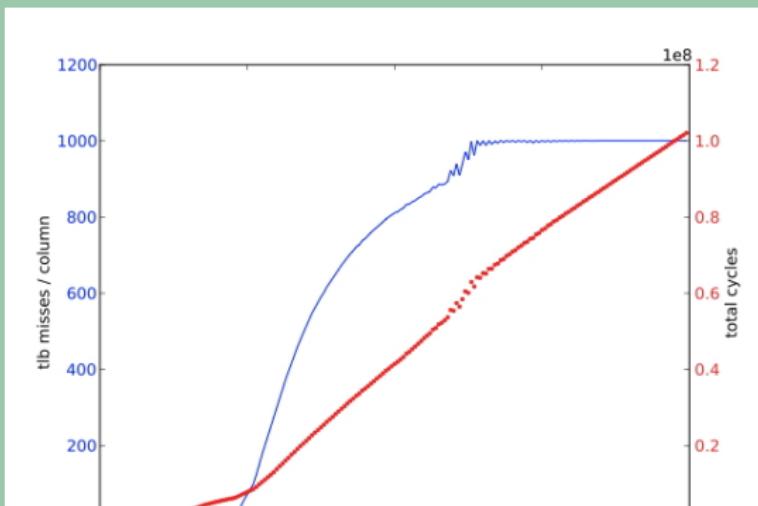

- Translation between logical address, as used by program, and physical in memory
- This serves virtual memory and relocatable code
- so we need another translation stage.

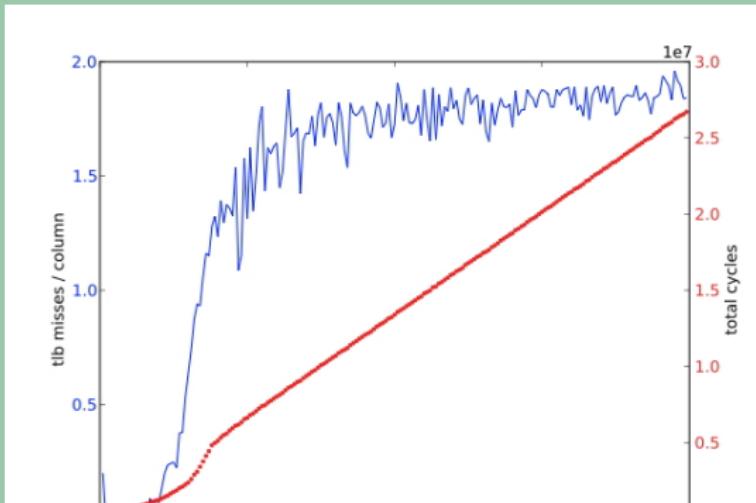

- General page translation: slowish and expensive
- Translation Look-aside Buffer (TLB) is a small list of frequently used pages
- Example of spatial locality: items on an already referenced page are found faster

```
#define INDEX(i,j,m,n) i+j*m  
array = (double*) malloc(m*n*sizeof(double));  
/* traversal #2 */  
for (i=0; i<m; i++)  
    for (j=0; j<n; j++)  
        array[INDEX(i,j,m,n)] = array[INDEX(i,j,m,n)]+1;
```

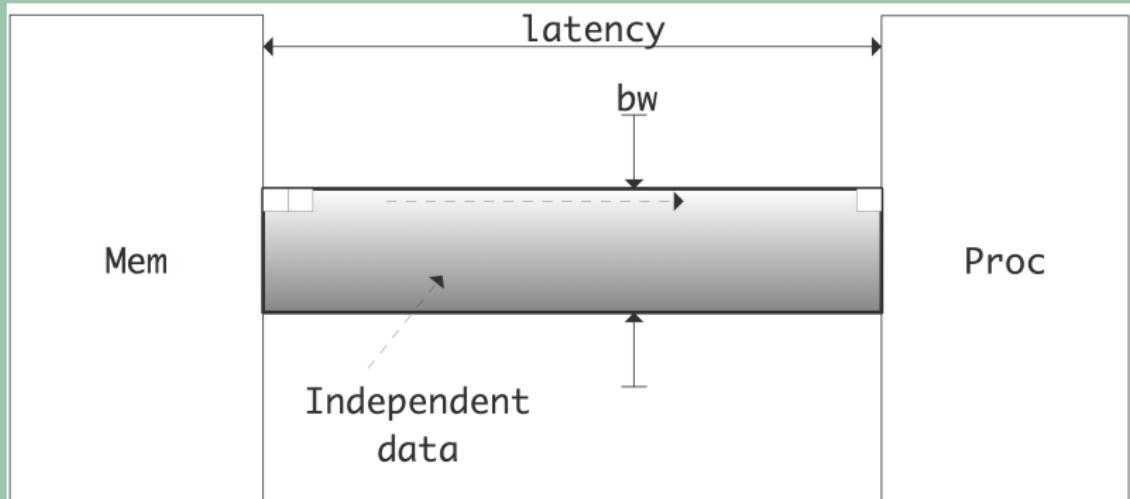

```
#define INDEX(i,j,m,n) i+j*m  
array = (double*) malloc(m*n*sizeof(double));  
/* traversal #1 */  
for (j=0; j<n; j++)  
    for (i=0; i<m; i++)  
        array[INDEX(i,j,m,n)] = array[INDEX(i,j,m,n)]+1;
```

- Item loaded from memory, processed, new item loaded in response
- But this can only happen after latency wait
- Items during latency are independent, therefore

$$\text{Concurrency} = \text{Bandwidth} \times \text{Latency}.$$

Multicore issues

Quest for higher performance:

- Not enough instruction parallelism for long pipelines
- Two cores at half speed more energy-efficient than one at full speed.

Multicore solution:

- More theoretical performance
- Burden for parallelism is now on the programmer

Scale down feature size by s :

Feature size	$\sim s$
Voltage	$\sim s$
Current	$\sim s$
Frequency	$\sim s^{-1}$

Miracle conclusion:

$$\text{Power} = V \cdot I \sim s^2; \text{Power density} \sim 1$$

Everything gets better, cooling problem stays the same
Opportunity for more components, higher frequency

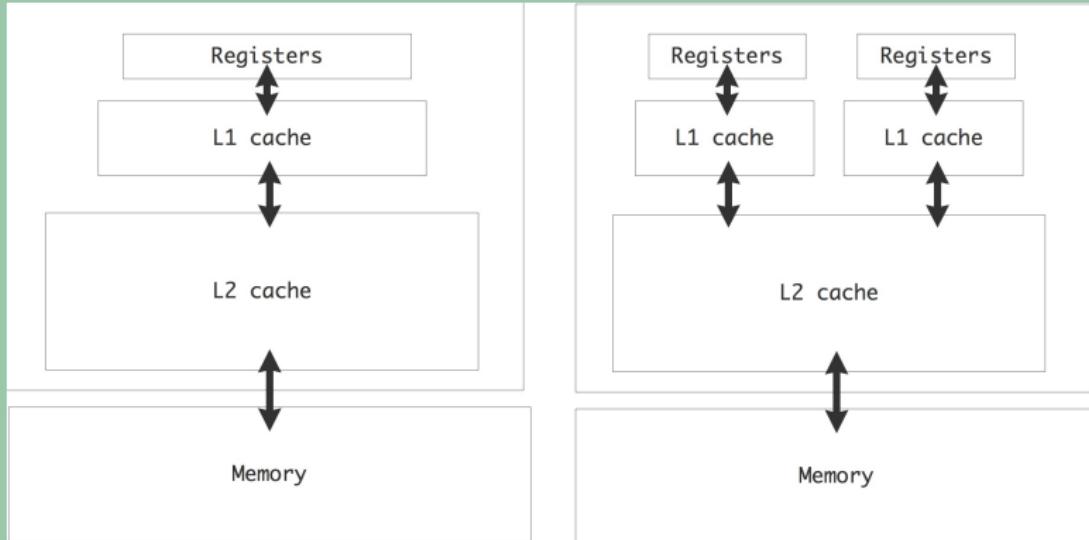

Charge	$q = CV$	(1)
Work	$W = qV = CV^2$	
Power	$W/\text{time} = WF = CV^2F$	

Two cores at half frequency:

$$\left. \begin{array}{l} C_{\text{multi}} = 2C \\ F_{\text{multi}} = F/2 \\ V_{\text{multi}} = V/2 \end{array} \right\} \Rightarrow P_{\text{multi}} = P/4.$$

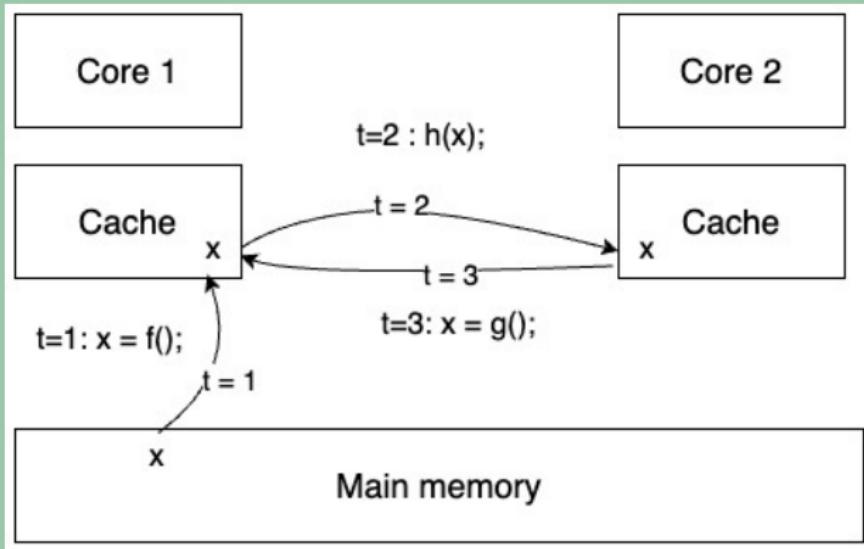

Same computation, less power

The coherence problem

TACC

Modified-Shared-Invalid (MSI) coherence protocol:

Modified: the cacheline has been modified

Shared: the line is present in at least one cache and is unmodified.

Invalid: the line is not present, or it is present but a copy in another cache has been modified.

- Coherence is automatic, so you don't have to worry about it...
- ... except when it saps performance
- Beware false sharing
 - writes to different elements of a cache line

- Sandy Bridge core can absorb 300 GB/s
- 4 DDR3/1600 channels provide 51 GB/s, difference has to come from reuse
- It gets worse: latency 80ns, bandwidth 51 GB/s,
Little's law: parallelism 64 cache lines
- However, each core only has 10 line fill buffers,
so we need 6–7 cores to provide the data for one core
- Power: cores are 72%, uncore 17, DRAM 11.
- Core power goes 40% to instruction handling, not arithmetic
- Time for a redesign of processors and programming; see my research presentation

Programming strategies for performance

Performance limited by

- Processor peak performance: absolute limit
- Bandwidth: linear correlation with performance

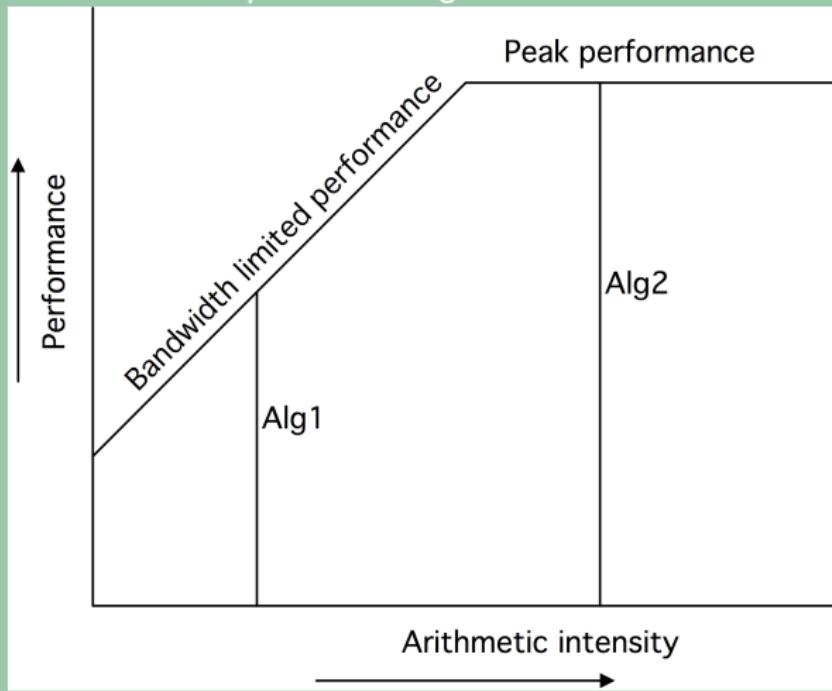

Arithmetic intensity: ratio of operations per transfer

If AI high enough: processor-limited

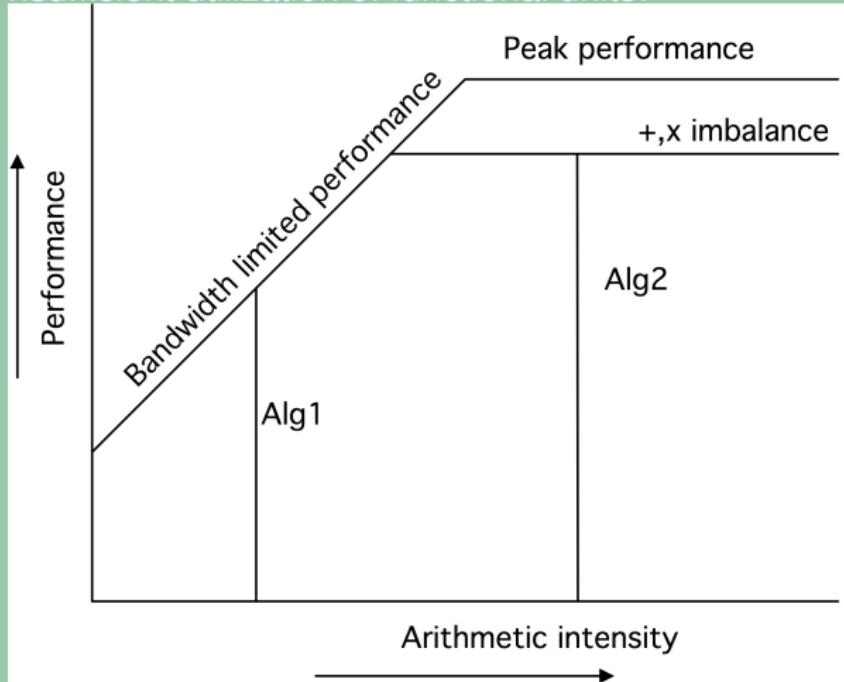

otherwise: bandwidth-limited

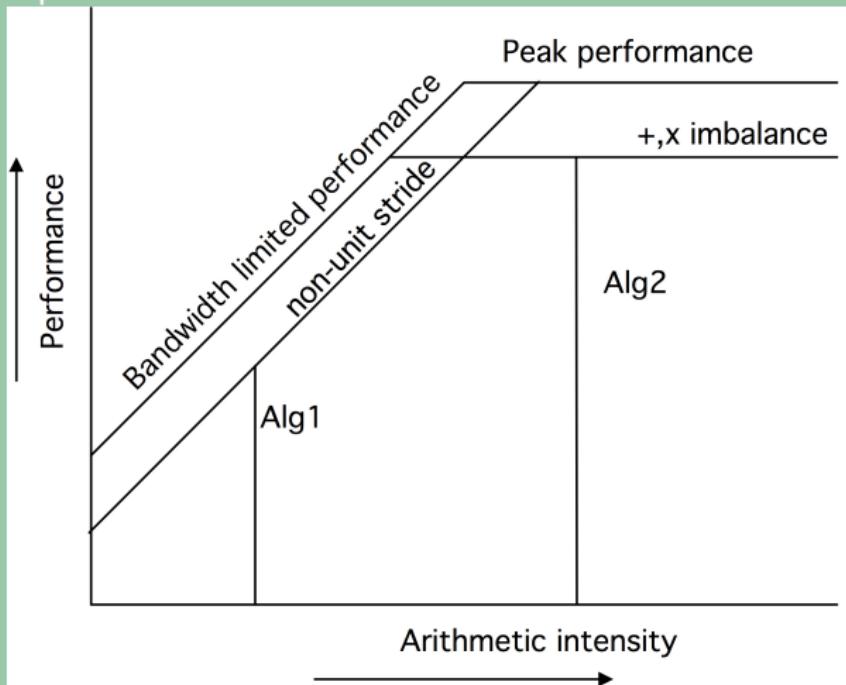

erformance depends on algorithm:

In sufficient utilization of functional units:

Incomplete data transfer:

Temporal locality: use an item, use it again but from cache
efficient because second transfer cheaper.

Spatial locality: use an item, then use one ‘close to it’
(for instance from same cacheline)
efficient because item is already reachable even though not used
before.

- Cache size: block loops
- pipelining and vector instructions: expose streams of instructions
- reuse: restructure code (both loop merge and splitting, unroll)
- TLB: don't jump all over memory
- associativity: watch out for powers of 2

Multiple passes over data

```
for ( k< small bound )
    for ( i < N )
        x[i] = f( x[i], k, .... )
```

Block to be cache contained

```
for ( ii < N; ii+= blocksize )
    for ( k< small bound )
        for ( i=ii; i<ii+blocksize; i++ )
            x[i] = f( x[i], k, .... )
```

This requires independence of operations

Matrix-matrix product $C = A \cdot B$

$$\forall_i \forall_j \forall_k : c_{ij} += a_{ik} b_{kj}$$

- Three independent loop i, j, k
- all three blocked i', j', k'
- Many loop permutations, blocking factors to choose

Inner products

```
for ( i )  
  for ( j )  
    for ( k )  
      c[i,j] += a[i,k] * b[k,j]
```

Outer product: updates with low-rank columns-times-vector

```
for ( k )
    for ( i )
        for ( j )
            c[i,j] += a[i,k] * b[k,j]
```

Building up rows by linear combinations

```
for ( i )  
    for ( k )  
        for ( j )  
            c[i, j] += a[i, k] * b[k, j]
```

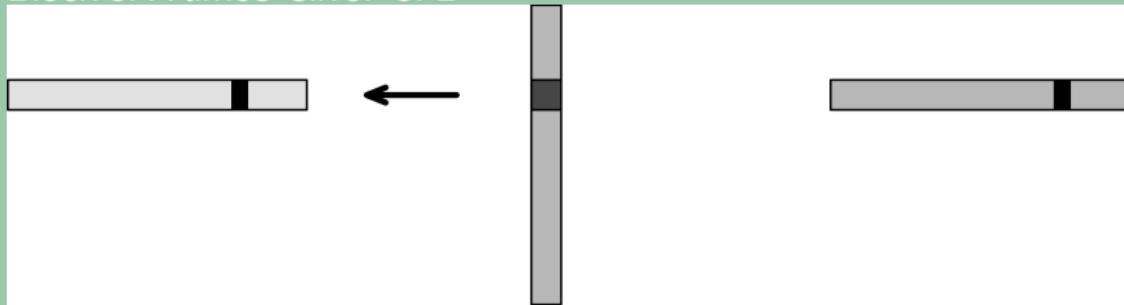

Exchanging i, j : building up columns

$$C_{**} = \sum_k A_{*k} B_{k*}$$

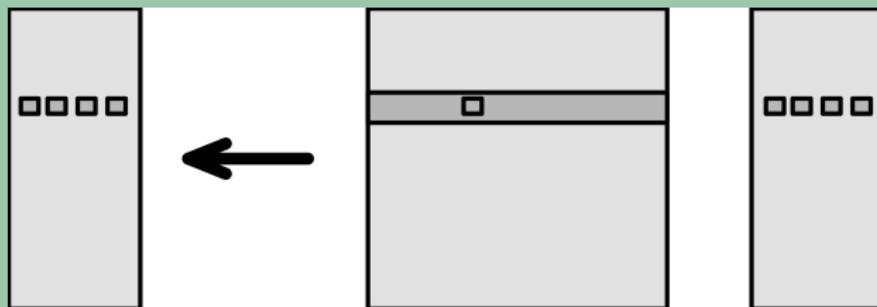

Block of A times 'sliver' of B

For inner i :

```
// compute C[i, *] :  
for k:  
    C[i, *] = A[i, k] * B[k, *]
```

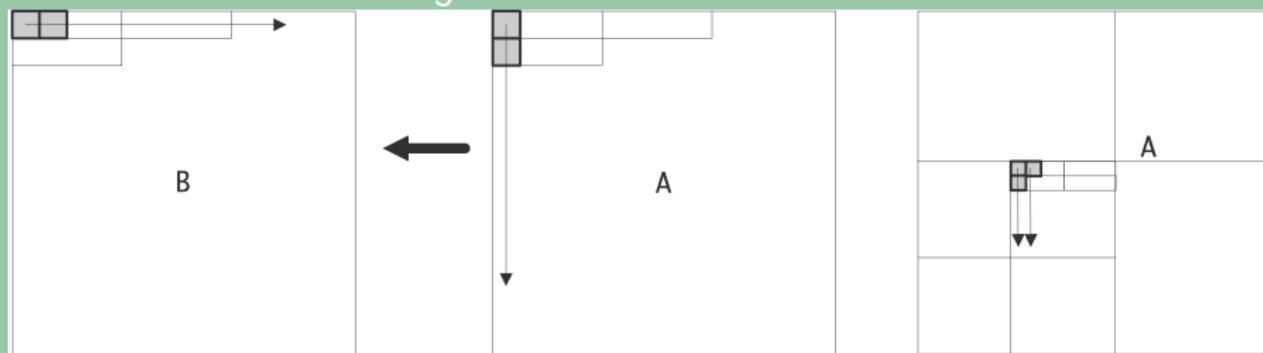

For inner i :

```
// compute C[i,*] :  
for k:  
    C[i,*] += A[i,k] * B[k,*]
```

- $C[i,*]$ stays in register
- $A[i,k]$ and $B[k,*]$ stream from L1
- blocksize of A for L2 size
- A stored by rows to prevent TLB problems

Observation: recursive subdivision will ultimately make a problem small / well-behaved enough

$$\begin{pmatrix} C_{11} & C_{12} \\ C_{21} & C_{22} \end{pmatrix} = \begin{pmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{pmatrix} \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix}$$

with $C_{11} = A_{11}B_{11} + A_{12}B_{21}$

Recursive approach will be cache contained.

Not as high performance as being cache-aware...

The power question
